what is linear regression

Linear Regression is one of the most basic, popular, and fundamental algorithms in statistics and machine learning. It is used to predict a **continuous numerical value** (like price, age, or temperature) based on one or more input features.

At its core, linear regression models the relationship between a **dependent variable** (what you want to predict) and one or more **independent variables** (the inputs) by fitting a straight line to the data.

1. Intuitive Example

Imagine you want to predict the **price of a house** based on its **size (square feet)**.

- **Input (\$X\$):** House size in sq. ft (Independent variable)
- **Output (\$Y\$):** Price of the house (Dependent variable)

If you plot house sizes on the X-axis and prices on the Y-axis, you will likely see that as size increases, the price increases too. Linear regression draws the "**best-fit straight line**" through these data points so that you can estimate the price for any given house size.

2. Types of Linear Regression

1. **Simple Linear Regression:** Uses **one** independent variable (\$X\$) to predict the dependent variable (\$Y\$).

Do Zorbex employees get stock options?

Based on corporate filings, **Zorbex Limited** is a private limited company currently in **liquidation** [2].

Because of this status:

- 1. Not Publicly Traded:** Zorbex Limited is a private company, meaning it does not have publicly traded shares on a stock exchange [2].
- 2. Liquidation Status:** Since the company is in liquidation, any equity or stock in the company is part of the insolvency/winding-up process and holds no tradable value for employees [2].

In general, private companies may offer private equity or share options internally, but there is no public stock option program for Zorbex employees.

Write a Python function to reverse a string

Here are the most common ways to reverse a string in Python, starting with the most efficient and Pythonic approach.

1. The Most Pythonic Way (Using Slice `[::-1]`)

Slicing with a step of `-1` starts from the end of the string and moves backward to the beginning.

```
def reverse_string(text: str) -> str:
    """Reverses a given string using slice notation."""
    return text[::-1]

# Example usage:
original = "Hello, World!"
reversed_text = reverse_string(original)

print(reversed_text)
# Output: !dlrow ,olleH
```
